**Abstract.** Neoadjuvant chemotherapy (NAC) of breast cancer (BC) improves outcomes, especially in patients with locally advanced and inflammatory cancer. Further insight into clinic-pathological factors influencing outcomes is essential to define the optimal therapeutic strategy for each category of patients and to predict the response to the treatment. In total, 117 patients with BC were treated with NAC with or without trastuzumab between 2010 and 2015. The histologic response to NAC was defined as a pathological complete response (pCR) when there was no evidence of residual invasive tumor in the breast or axillary lymph nodes. Relapse-free survival (RFS) was estimated using the Kaplan-Meier method and compared using log rank analysis. P-value <0.05 was considered statistically significant. The median age of the 117 patients enrolled in the present study was 52 years (age range, 35-85 years). The overall response rate (complete and partial responses) assessed by radiological and pathological evaluation were 76 and 72%, respectively. pCR was achieved in 35 out of 117 patients (~30%). In total, 6 patients (5%) developed progressive disease during chemotherapy. The RFS was 85 months (SE=3; 95% CI 79-91). The median was not reached and the mean follow-up time was 55 months (median 52 months; range 11-100 months). In this time, 20 patients (17%) experienced tumor recurrence. From the univariate analysis, the pathological response was significantly associated with receptor-based subtype,

menopausal status and T-stage. From the multivariate analysis by using linear multiple regression and including receptor-menopausal status and T-stage, the model was not significant (P=0.062). However, by using the multiple logistic regression, and including age, pCR was significantly associated with ER+HER2neg (P=0.006), T2 (P=0.043) and T3 (P=0.018). T-stage, menopausal status and receptor status are significantly associated with the pathological response in patients with inoperable BC treated with NAC.

## Introduction

Preoperative neoadjuvant chemotherapy (NAC) is established as a therapeutic avenue for selected high-risk BCs, with tumors  $\geq 2$  cm and for locally advanced (including initially ineligible for resection) disease (1). Breast cancer is divided into three groups based on the expression or not of different markers such as estrogen receptor (ER), progesterone receptor (PgR) and human epidermal growth factor receptor 2 (HER2): Hormone receptor positive/HER2 negative, HER2 positive, and triple-negative that does not have any of the three molecular markers. The therapeutic intervention consists of endocrine therapy for all Hormone Receptor (HR) positive tumors with some patients requiring chemotherapy (adriamycin, cyclophosphamide, paclitaxel or docetaxel); chemotherapy plus HER2-targeted therapy for HER2 positive and chemotherapy alone for triple-negative breast cancer (2). The use of NAC in BC treated with surgery is currently increasing because of the chance of measuring early in-vivo response to systemic treatment and to achieve higher rates of breast conserving surgery (3). Neoadjuvant treatment modalities require a close collaboration between oncologists, surgeons, radiologists and pathologists to attain the best results.

The most important parameter for successful treatment and improvement in overall survival (OS) is the achievement of a pCR although the identification of clinical and

**Key words:** breast cancer, neoadjuvant chemotherapy, triple negative, estrogen receptor, progesterone receptor

pathological parameters predictive of treatment response and best survival outcomes remains not still clearly defined. Preliminary identification of patient subgroups with high pCR rates could preferably refer them to neoadjuvant treatment strategies. Despite extensive clinical investigations, it has not yet been clarified whether NAC would result in improved survival in comparison with the standard adjuvant setting in any subgroups of patients with BC (4).

However, comparable data between adjuvant and neoadjuvant settings (5,6) have changed the BC treatment, with an increased use of NAC. These data have stimulated the formation of an international expert panel consensus to provide recommendations on the use of neoadjuvant therapy. In short, the panel suggests that NAC should be considered in any individual patient for whom adjuvant chemotherapy is indicated (7).

BC is increasingly recognized as a heterogeneous disease showing a different response to treatment according to defined clinical and pathological parameters. Additionally, changes in some pathological parameters during each BC history require new tumor biopsy and even complicate the BC treatment. The prognostic value of these changes is also not well defined (8,9). Chemotherapy is especially effective in the treatment of endocrine insensitive tumors, and such therapeutic benefit can be assumed for patients with triple-negative, or HR negative and HER2 positive BC (10,11). In case of HER2 positive tumors, an anti-HER2 agent can be administered as part of the preoperative treatment, and according to preliminary clinical data, dual HER2 blockade can offer an additional therapeutic value (12). However, dose escalation, kind of chemotherapy regimen and number of cycles are still debating matters.

In this study, we reported retrospective data concerning 117 BC patients treated with NAC in a single institution. All available clinic-pathological parameters were analyzed to evaluate the correlation, if any, with response and survival outcomes.

## Patients and methods

**Patient selection.** Data from 117 patients with BC diagnosed by needle aspiration cytology and histopathology biopsy and treated from March 2010 to December 2015 with various regimens of NAC at a single center were reviewed. All patients provided informed consent and Local Ethical Committee of San Giovanni di Dio Hospital of Frattamaggiore gave formal approval to this retrospective study (approval no. 1250 on 20th February 2018). Eligible patients were women aged  $\geq 18$  years with localized primary BC suitable for primary medical treatment with or without regional lymph node metastases, with adequate bone marrow, renal, hepatic, and cardiac functions, no other uncontrolled medical or psychiatric disorders and with an ECOG performance status of 0-1. The main exclusion criteria were distant metastases, other malignancy in the past two years (except for radically treated basal or squamous cell carcinoma of the skin or carcinoma *in situ* of the cervix), and pregnancy or lactation.

**Clinical assessment.** At baseline all patients underwent clinical assessment, hematology and chemistry and core needle biopsies that were performed either free-hand or under ultra-sound guidance. For each patient we recorded baseline

tumor size by ultrasound and mammography, nodal status involvement by ultrasound-guided fine-needle aspiration or, when negative, by sentinel node biopsy, type of NAC and type of surgery (S). pCR defined as the absence of invasive cells in the breast and the lymph nodes regardless of Ductal Carcinoma In Situ (DCIS). Immunohistochemistry (IHC) subtypes were defined according to Estrogen (ER) and progesterone receptor (PgR), Ki-67 level (nuclear antigen expressed in cycling cells), and HER2 status.

Clinical and radiological response evaluations were performed after two, four and six courses of treatment. All patients underwent Positron Emission Tomography (PET) at baseline and before surgery.

Tumors were staged according to Tumor Node Metastasis (TNM) staging system (7th edition). ER and PgR status were determined by IHC and was considered positive if tumor cells were  $\geq 1\%$ . Tumors with a score of 3+ (strong homogeneous staining) were considered HER2-positive. In case of 2+ scores (moderate homogeneous staining) chromogenic *in situ* hybridization (CISH) was used to determine amplification. The tumor margins were defined as a clear pathologic margin if the distance was  $>2$  mm by microscopy evaluation. The clinic-pathological data at baseline are summarized in Table I. The clinical pathological protocols used for the collection of the data were recorded at the Unit of Oncology of San Giovanni di Dio Hospital in Frattamaggiore.

**Therapeutic management of patients.** Neoadjuvant regimens of chemotherapy were summarized in Table II. Number of chemotherapy cycles administered was guided by tumor evaluation and ranged between 4 and at most 6 cycles. Recommendation for surgery was made after evaluation of a team of BC specialists including radiologists, medical oncologists and surgeons. Treatment decisions were mainly based on patient's desires and surgical considerations involving the breast-tumor index, age, multifocality, localization and response were obtained after NAC. All patients with proven axillary lymph node metastases prior to NAC underwent to an axillary lymph node dissection (ALND) at levels I and II with level III sampling after NAC. Level III sampling was done to stage for adjuvant radiotherapy indications. Patients undergoing to breast-conserving surgery received radiation to the breast with a boost to the tumor bed. The indication for loco-regional radiation therapy (chest wall and regional nodal basins) was based on the original staging. Hormone receptor-positive patients received adjuvant endocrine treatment for at least 5 years and HER2-positive patients were treated with trastuzumab for 1 year.

**Statistical analysis.** RFS was estimated by the Kaplan-Meier method and compared using the log rank analysis. P-values were considered statistically significant when  $<0.05$ . The statistical analyses were performed using the chi-square test and conducted by SPSS software (version 17.0).

## Results

**Patient characteristics.** The median age of the patients was 52.8 years (range 35-85 years). Fifty-three (45%) were pre- and 64 (55%) were post-menopausal women. Most patients had ductal invasive carcinoma (approximately 90%). T2 and T4

High (>30%)	41

ER, estrogen receptor; HER2, human epidermal growth factor receptor; PR, progesterone receptor; Ki67, proliferation marker protein Ki-67.

tumors were the most represented in our series: 42 and 36%, respectively. Lymph node involvement classified as N2/N3 was present in 56% of the patients. Hormone positive, HER2 negative tumors were 57% of the patients. HER2 positive tumors were about 30% of the patients. Intermediate-high proliferating tumors, expressed by Ki-67, were about 79% (Table I).

*Effects of NAC regimen.* Chemotherapy used for NAC was predominantly an anthracycline-based regimen (67% of the patients) as shown in Table II. A HER2 targeted therapy was used in 16% of the patients. In 19% of the patients a liposomal doxorubicin was used. In 14% of the patients, belonging to the last enrolled patients, the novel treatment with double antibodies (pertuzumab and trastuzumab) plus docetaxel was used (Table II). The number of patients treated with trastuzumab was low because the combination of trastuzumab with anthracyclines could induce sub-clinical or clinical cardiac failure.

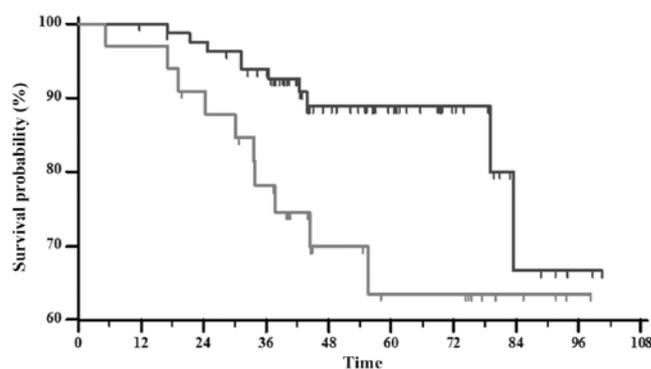

Figure 1. Kaplan-Meier curve of relapse-free survival estimated by dividing patients into two categories and compared using log rank test, P=0.0210. Patients with complete and partial response (dark grey) compared with the stable and progressive disease group (light grey).

All patients had a positive PET scan at the tumor site. About 73% of the patients showed significant uptake at the level of the axilla. Overall Response Rate (ORR) was 76 and 72% when assessed by radiological and pathological evaluation, respectively. In 40 out of 117 patients (34%) a conservative treatment was allowed. In details, we recorded 46 CRs and 43 partial responses (PRs) by radiology (Table III). Thirty-five pCRs (pCR rate about 30%) and 49 pPRs were documented by pathology (Table III). Among the 15 patients with triple-negative tumors, a conservative surgical treatment was performed in 6 patients and in 6 instances a pathological response was obtained. Three triple negative patients relapsed during follow-up: One patient at lymph nodes, one at lymph nodes and bone and one at bone and visceral sites.

*Statistical correlation between pathological responses, and clinical and pathological features.* Comparing all together complete and partial pathologically responders to the patients with SD and PD, the RFS difference was highly statistically significant (P=0.0210) as shown in Fig. 1. However, pCR does not significantly correlate with either

Table III. Response rates by method of assessment.

Clinical assessment	Total number	ORR (%)	CR number	PR number	SD number	PD number
Radiological	117	76	46	43	23	5
Pathological	117	72	35	49	28	5

ORR, overall response rate; CR, complete response; PR, partial response; SD, stable disease; PD, progressive disease.

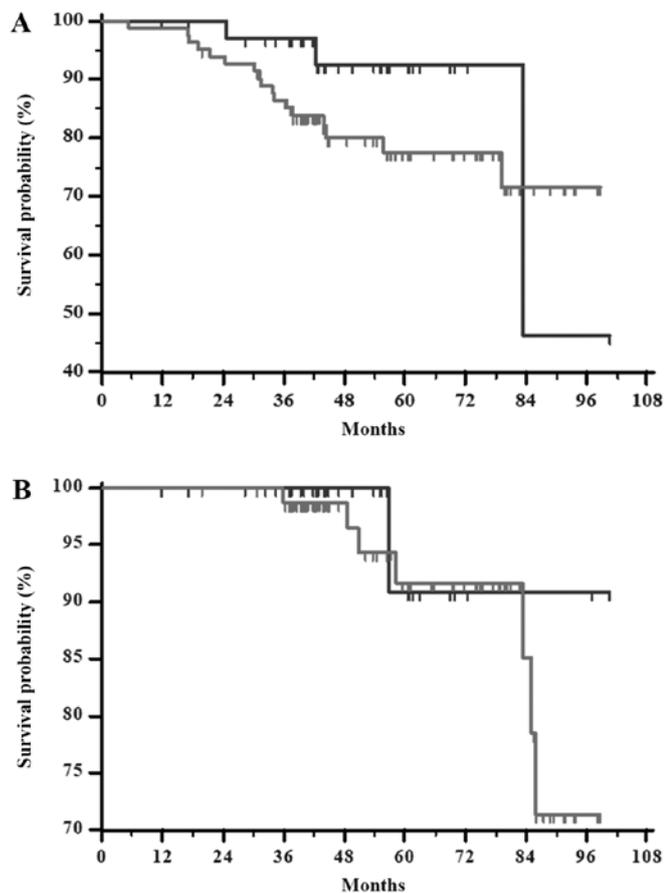

Figure 2. Kaplan-Meier curve estimated by dividing patients into two categories. Patients with a complete pathological response (dark grey) compared with the overall population, PR+SD+PD (light grey). (A) Relapse-free survival is presented,  $P=0.1852$ . (B) Overall survival is presented,  $P=0.5599$ . PR, partial response; SD, stable disease; PD, progressive disease.

RFS or overall survival (OS) ( $P=0.1852$  and  $P=0.5599$ , respectively) (Fig. 2A and B, respectively), when compared to patients with pPRs + pSD + PD. There was no significant difference between clinical response and Ki-67 labeling index ( $P=0.9705$ ). Likewise, the statistical analysis showed no differences between pathological responses and Ki-67 labeling index ( $P=0.2867$ ) (Table IV).

By chi-square test the combination of an anthracycline-based regimen plus an anti-HER2 therapy was significantly associated with pCR ( $P=0.00025712$ ).

The RFS mean for all groups (117 patients) was 85 months (SE=3; 95% CI 79-91). The median was not reached and the mean follow-up time was 55 months (median 52 months; range 11-100 months). In this time, about twenty patients

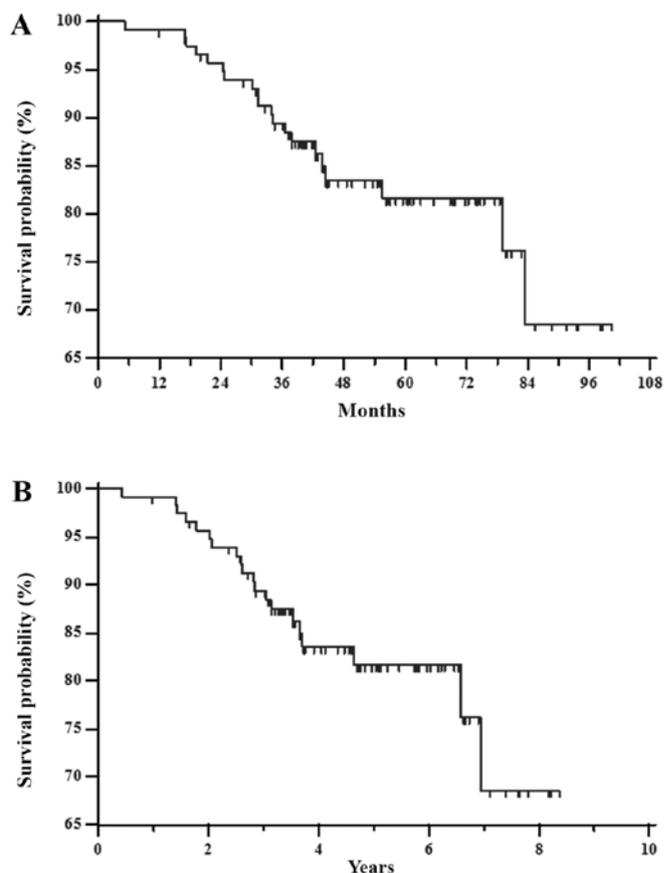

Figure 3. Kaplan-Meier curve of RFS estimated for all patients using log rank test,  $P<0.001$ . (A) RFS mean for all group (117 patients) was 85 months (SE=3; 95% CI 79-91). The median was not reached; the mean follow-up time was 55 months (median 52 months; range 11-100 months). In this time, twenty patients (17%) experienced tumor recurrence. (B) 1-7 year RFS rates were 99.1, 95.7, 89.4, 83.5, 81.7, 81.7 and 68.6%, respectively. RFS, relapse-free survival.

(17%) experienced tumor recurrence (Fig. 3A). The 1-7 year RFS rates were 99.1, 95.7, 89.4, 83.5, 81.7, 81.7 and 68.6%, respectively (Fig. 3B).

At univariate analysis, pathological response was significantly associated with receptor-based subtype ( $P=0.0001$ ), menopausal status ( $P=0.0368$ ) and T-stage ( $P=0.0007$ ). On the contrary, obesity ( $P=0.6128$ ), histological subtype ( $P=0.3238$ ), Ki67 status ( $P=0.1747$ ), N-stage ( $P=0.8914$ ) and age ( $P=0.0730$ ) did not seem to correlate with pathological response in this patients' series (Table V).

At multivariate analysis by using linear multiple regression and including receptor status, menopausal status and T-stage, the model was not significant for menopausal status ( $P=0.062$ ).

Table IV. Clinical and pathological response after neoadjuvant chemotherapy by Ki67 labeling index.

Therapy response	Ki67 labeling index			P-value
	Low	Intermediate	High	
Clinical response				
PR + CR	17	37	30	0.9705
SD + PD	7	15	11	
Pathological response

T4	16	26	
N-stage			
N0	4	14	0.8914
N1	8	18	
N2/N3	20	44	
NX	3	6	
BMI			
Overweight	15	41	0.6128
Normal	20	41	
Age			
>50	14	48	0.0730
<50	21	34	

pCR, pathological complete response; ER, estrogen receptor; HER2, human epidermal growth factor receptor; PR, progesterone receptor; Ki67, proliferation marker protein Ki-67; BMI, body mass index.

However, by using the multiple logistic regression, and including age, pCR was significantly associated with ER+HER2neg (P=0.006), T2 (P=0.043), and T3 (P=0.018).

**Histological heterogeneity of breast cancer.** Fourteen tumor histotypes changed: 5 mixed ductal/lobular tumors became ductal (4 cases) and lobular (1 case), 8 ductal carcinomas became lobular (7 cases) and ductal hyperplasia (1 case), one lobular carcinoma became ductal. ER/PgR and HER2 status changed in 15 out of 117 patients (12%). In particular, 5 patients became HER2 positive and 5 patients became negative (respectively about 4%). ER/PgR status changed in 7 patients (6%) with 5 patients becoming hormone-responsive.

## Discussion

In this retrospective review of clinical practice treatment with NAC of BC patients, we obtained a high radiological and pathological response rate. The association of an anthracycline-based regimen plus an anti-HER2 therapy was significantly associated with high pCR rate. Moreover, clinical and pathological response was independent from proliferation rate as expressed by Ki-67 status, reflecting an association to still unspecified molecular features more than to the simple proliferation rate of the neoplasm as previously reported. In this series, pCR does not significantly correlate with both RFS and OS, differently from most published studies. A meta-analysis of randomized clinical trials for resectable BC comparing the survival benefit of NAC vs. postoperative chemotherapy showed that NAC cycles, the total number of chemotherapy cycles, administration of tamoxifen, administration of adjuvant chemotherapy, or type of NAC regimen, did not influence OS. The pooled HR estimate for RFS was influenced by anthracycline-containing regimens. Patients with a pCR had superior survival outcomes compared with patients who had residual disease (5). However, we found a significant correlation between the pathological response and the RFS when compared to stable or progressive disease. In the present study, an anthracycline-based regimen plus the anti-HER2 agent trastuzumab showed better results in term of pCR. Interestingly, when treating HER2 positive tumours the best response is given by trastuzumab and pertuzumab combined with docetaxel. The responses observed in this subset of patients is online with previously published trials (13,14). Moreover, the synergism between pertuzumab and trastuzumab is not surprising if we consider that this kind of tumours are likely driven by an overexpression and hyperactivation of peptide growth factor receptors and, therefore, are more likely responsive to the block of these pathways. HER2-positive breast cancers are more aggressive than other types of BC and anti-HER2 agents bind different domains of HER2 receptor inducing a dual blockade of the receptor and consequent inhibition of the downstream signaling processes associated with tumor growth and progression. The concomitant use of the two antibodies can have synergistic effects based upon the different biological effects triggered by the two different weapons: Trastuzumab activates immunological effects (i.e.: ADCC) and blocks receptor activation and pertuzumab inhibits receptor dimerization thus specifically blocking the different signal transduction activated by the receptors overcoming resistance to trastuzumab due to HER2 truncations (15). However, it is still

not clear and defined how to predict the response of BC to NAC regimens and how to select the best combination in patients. Molecular research on genetic characteristics of BC could be useful in the future to predict the best choice in this subset of patients as already experienced some years ago for taxanes (16). In the present study we recorded also a change in some cases of the pathological molecular features of BC after the treatment of the patients with NAC. In fact, HER2 status changed in 8% of cases. ER/PgR status changed in 6% of the patients. These data are similar to previously reported similar series (17). The difference between IHC from preliminary biopsy and definitive surgical specimens may reflect not only different kind of samples but also a change in tumor itself conditioned by NAC.

Obesity does not seem to correlate with pathological response in this patients' series. Previous studies assessed the value of obesity in patients treated with NAC. Obesity seems to have a negative impact on survival that is independent from chemotherapy dosing (18-21).

Although the reduced number of patients and the retrospective analysis limited the value of this study, the data reported reflect the clinical practice of a single institution and suggest evaluating T-stage, menopausal status and receptor status in patients with inoperable BC treated with NAC to predict the pathological response. Despite the increased knowledge of distinctive clinical and pathological parameters and insights into genetic variability of BC, a standardized model predictive of response to NAC is not presently available. A tailored evaluation of presumptive better chemotherapeutic regimens for each tumor subtype is desirable in the next future.
